## Contents

Diffusion Pseudo Time (DPT) is a pseudo time metric based on the transition probability of a diffusion process?. destiny supports DPT in addition to its primary function of creating `DiffusionMaps` from data.

```
In [2]: library(destiny) # load destiny...
        data(guo)       # ...and sample data
```

DPT is in practice independent of Diffusion Maps:

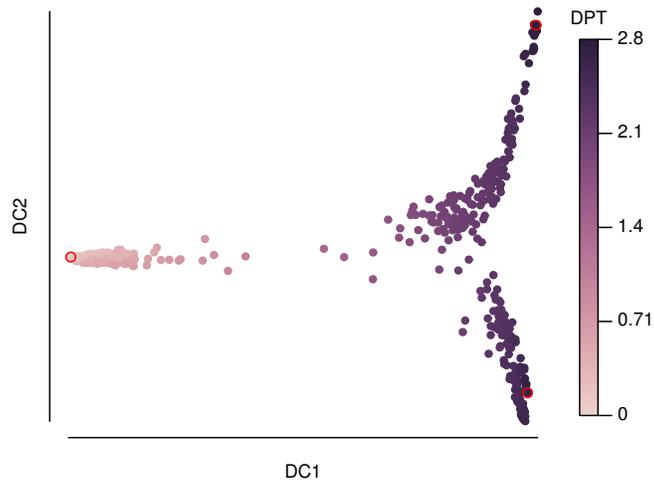

However in order not to overcomplicate things, in destiny, you have to create DPT objects from `DiffusionMap` objects.

(If you really only need the DPT, skip Diffusion Component creation by specifying `n_eigs = 0`)

```
In [4]: dm <- DiffusionMap(guo)
        dpt <- DPT(dm)
```

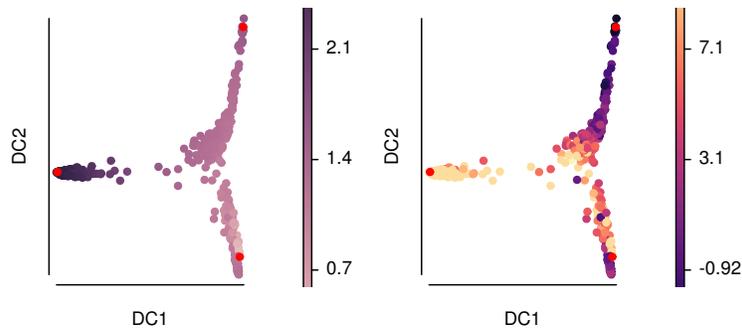

The resulting object of a call like this will have three automatically chosen tip cells. Plotting without parameters results in the DPT of the first root cell:

```
In [5]: plot(dpt, pch = 20) # "pch" for prettier points
```

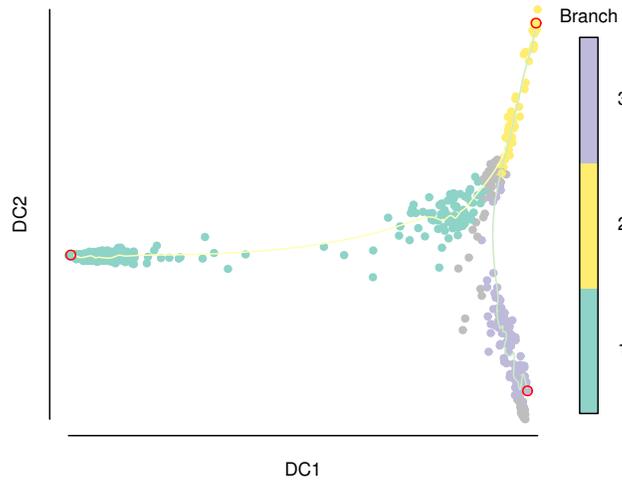

Other possibilities include the DPT from the other tips or everything supported by `plot.DiffusionMap`:

```
In [7]: par(mfrow = c(1,2), pch = 20, mar = c(2,2,0,1))
       plot(dpt, col_by = 'DPT3')
       plot(dpt, col_by = 'Gata4', pal = viridis::magma)
```

The DPT object also contains a clustering based on the tip cells and DPT, and you can specify where to draw paths from and to:

```
In [9]: plot(dpt, root = 2, paths_to = c(1,3), col_by = 'branch', pch = 20)
```

You can further divide branches. First simply plot branch colors like we did above, then identify the number of the branch you intend to plot, and then specify it in a subsequent `plot` call. In order to see the new branches best, we specify a `dcs` argument that visually spreads out all four branches.

In [10]: `plot(dpt, col_by = 'branch', divide = 3, dcs = c(-1,3,-2), pch = 20)`
